Abstract

Objectives: To describe the general characteristics and frequency of noninfectious complications in children with end stage renal disease (ESRD) in chronic peritoneal dialysis. **Material and methods:** A retrospective case series study describing noninfectious complications in the population of children, aged between 1 month and 17 years 11 months, with end stage renal disease from the peritoneal dialysis program at Cayetano Heredia Hospital between 2000 and 2007.

Results: We studied 80 children, 41 male and 39 female; 92 catheters were implanted; the average age of the children was 10.3 years and the largest age group was from 5 to 12 years. The leading cause of end stage renal disease was primary glomerulopathy. The Tenckhoff two-cuff spiral catheter was the most commonly used catheter; continuous ambulatory peritoneal dialysis was the most common mode of dialysis; there were 12 catheter replacements, the most frequent causes being peritonitis and catheter obstruction. The frequency of noninfectious complications was 40.3%; the three most common complications were ultrafiltration failure (low transporter type), umbilical hernia, and catheter obstruction.

Conclusions: The frequency of noninfectious complications was 40.3%; the most common complication was ultrafiltration failure.

Keywords: Noninfectious complications; Children; Peritoneal dialysis; Renal insufficiency; Chronic; Tenckhoff catheter

Introduction

Peritoneal dialysis (PD) is the preferred renal replacement therapy in children with end stage renal disease (ESRD). It has been used for renal replacement in children since 1978 and has been shown to have a number of advantages over hemodialysis – above all in children where the vascular access is difficult, in patients receiving anticoagulants, and in children without access to a hemodialysis center. PD also achieves better control of blood pressure, acidemia, and electrolyte balance. As a result, it is possible to achieve a higher degree of social and school rehabilitation at lower financial cost [1-6].

As well as advantages, there are also disadvantages, however. These are complications, which can be classified as infectious or noninfectious: noninfectious complications include complications with the surgical technique, catheter malfunction, defects in the abdominal wall, ultrafiltration failure, and electrolyte and metabolic complications. Studying and being familiar with these complications is important, as they imply therapy failure and an increase in financial costs [7-9].

No studies have been conducted on this subject in Peru. In Latin America, there have been two studies: one in Chile, describing the characteristics of the patients and their infectious complications, without reference to noninfectious complications; and a thesis in Brazil on surgical complications and related technical aspects. In addition, there have been a number of other studies in the world

examining complications in general, with little emphasis on noninfectious complications [10-14].

The objectives of the present study were to describe the characteristics of the population of children with ESRD in chronic peritoneal dialysis and the frequency of noninfectious complications related to surgical technique, catheter malfunction, defects in the abdominal wall, and failure of ultrafiltration at the Peritoneal Dialysis Unit of Cayetano Heredia Hospital (CHH), Lima, Peru between 2000 and 2007.

Materials and Methods

A descriptive study was conducted, namely a retrospective case series study of the population of children with ESRD undergoing chronic peritoneal dialysis therapy at CHH between January 2000 and December 2007.

The criteria of inclusion were as follows: (1) children with a diagnosis of ESRD requiring chronic peritoneal dialysis; (2) age over 1 month and less than 18 years; (3) peritoneal dialysis catheter placement at CHH.

Exclusion criteria were (1) children with ESRD in peritoneal dialysis referred from other hospitals; (2) placement of catheters without standardized techniques; (3) incomplete follow-up reports from the peritoneal dialysis unit.

Regarding placement of the PD catheter, for all children the catheter was put in place following the recommendations of the European Committee of the International Society for Elective Chronic

Peritoneal Dialysis in Pediatric Patients (34): type of surgery, minilaparotomy; general anesthesia; paramedian line catheter entry site, directing it downward and to the middle, with partial omentectomy. The procedure was performed by a pediatric surgeon; the interval between the placement of the catheter and the onset of dialysis was two weeks.

The instrument of data collection was previously elaborated; the source of information was the medical records from CHH and the patient's follow-up sheets at the Peritoneal Dialysis

Unit from the Support Services of Cayetano Heredia Peruvian University. We performed descriptive analysis means median and standard deviation to analyze the continued variables. The statistical program used was STATA version 11.

The general variables that allowed us to learn the most important characteristics of the population were: age upon entering peritoneal dialysis therapy, sex, primary diagnosis of ESRD, DP catheter, replacement of DP catheter, number of replacements of catheter, and omentectomy at the beginning of peritoneal dialysis.

The operational definition of variables and risk factors of noninfectious complications, excluding metabolic and electrolyte complications, was classified by reviewing the bibliographies in the following publications [8,9,15].

Noninfectious complications related to surgical technique:

- Hemoperitoneum: Presence of blood in the peritoneal fluid. Causes: injury of blood vessels when placing the catheter, coagulation disorders, sclerosing peritonitis, splenic rupture.

- Chyloperitoneum: Appearance of milky turbid liquid with normal cell counts in the absence of peritonitis due to the presence of triglyceride rich chylomicrons. Causes: microtrauma of lymphatic vessels when inserting the catheter [16], malignant neoplasm [17], cirrhosis, chronic pancreatitis [18], systemic amyloidosis [19], lymphatic obstruction due to fibrous adhesions caused by tuberculosis, [20] and the use of dihydropyridine calcium antagonists [21].

- External cuff extrusion: Appearance of external cuff through the outlet port.

- Extrusion of the catheter: Presence of the catheter through the outlet port.

- Abdominal wall hematoma

Noninfectious complications of catheter dysfunction:

- Abdominal hernias: The protrusion of an organ or tissue outside the abdominal cavity.

Risk factors: history of prior abdominal surgery, polycystic kidney disease [22,23], persistence of the vaginal process [24], male and aged less than six months [25]. Types by location: umbilical, inguinal and incisional.

- Leakage of dialysate: Leakage of dialysate outside the abdominal cavity through different areas of weakness of the abdominal cavity, including the hydrothorax.

Noninfectious complications due to ultrafiltration failure:

- Ultrafiltration failure: The most accepted definition is a UF (ultrafiltration) less than 400 ml with an exchange of 3.86% glucose

and a dwell time of 4 h [26]. It is classified according to the estimation of transport of small molecular weight solutes in:

- High Transporters: Low volume of drainage and high transport of solutes (UF failure type I): patients with UF less than 400 ml at 4 hours and a dialysate ratio plasma (d/p) of creatinine greater than 0.81.

- Low transporters: Low volume of drainage and low peritoneal transport (UF failure type II): patients with UF less than 400 ml at 4 hours and a d/p of creatinine greater than 0.49.

- Low volume of drainage with medium-low or medium-high transport

Results

The population of children with ESRD in peritoneal dialysis was 80: 41 male and 39 female. The average age of entry to peritoneal dialysis was 10.3 years, with the lowest age 7 months and the highest age 16 years 6 months. Regarding the distribution by age group, it was found that school children and adolescents accounted for 85% of all patients in PD (Table 1).

Age group	Frequency	Percentage
Less than 2 years	4	5%
2 to 5 years	8	10%
5 to 12 years	35	43.7%
Older than 12 years	33	41.3%
Total	80	100%

Table 1: Distribution of the 80 children on chronic peritoneal dialysis by age group

The most frequently used peritoneal dialysis modality was CAPD (continuous ambulatory peritoneal dialysis) in 67 children (83.8%).

The most common primary diagnosis of ESRD were the primary glomerulopathies and obstructive uropathies (Table 2).

Type of nephropathy	Frequency	Percentage
Primary glomerulopathy	39	48.8%
Obstructive uropathy	22	27.5%
Secondary glomerulopathy	9	11.2%
Congenital: hypoplasia or renal dysplasia	8	10%
Hereditary	2	2.5%
Total	80	100%

Table 2: Common causes of ESRD resulting in chronic peritoneal dialysis in the population of 80 children at Cayetano Heredia National Hospital

Regarding the type of catheter used, the three most common were the Tenckhoff two-cuff spiral catheter, the Tenckhoff two-cuff straight catheter, and the Tenckhoff one-cuff spiral catheter (Table 3).

Eleven children required catheter replacement: a single replacement was performed on 10 children and two replacements were performed

on one child. The most frequent reasons for replacement were infectious complications such as peritonitis, and noninfectious complications such as catheter obstruction (Table 4).

Type of PD catheter	Frequency	Percentage
Tenckhoff spiral catheter	56	60.9%
Tenckhoff two-cuff straight catheter	21	22.8%
Tenckhoff one-cuff spiral catheter	14	15.2%
Tenckhoff one-cuff straight catheter	1	1.1%
Goose-neck catheter	0	0%
Total	92	100%

Table 3: Type of peritoneal dialysis catheter inserted in 80 children with ESRD

Causes of catheter replacement	Frequency	Percentage
Peritonitis	5	41.7%
Peritonitis candida	2	16.7%
Catheter obstruction	2	16.7%
Catheter migration	1	8.3%
Membrane failure	1	8.3%
Other	1	8.3%
Total	12	100%

Table 4: Causes of catheter replacement in 80 children with ESRD on peritoneal dialysis

In our study over a period of 1968 months follow 92 catheters of chronic peritoneal dialysis were placed, the frequency of noninfectious complications was 40.3% of children [13]. The incidence was one complication each dialysis every 61.5 months.

The most common noninfectious complications were failure of ultrafiltration (low transporter type), umbilical hernia, catheter obstruction, hemoperitoneum, extrusion of the external catheter cuff, inguinal hernia, leakage of dialysate, abdominal wall hematoma and failure of ultrafiltration (high transporter type), and migration of the catheter (Table 5).

Noninfectious complication	Frequency	Percentage
Ultrafiltration failure, low transporter type	6	18.8%
Umbilical hernia	5	15.6%
Obstruction of the PD catheter	5	15.6%
Hemoperitoneum	4	12.5%
Extrusion of the external cuff	4	12.5%
Inguinal hernia	3	9.4%
Leakage of dialysate	2	6.3%
Abdominal wall hematoma	1	3.1%

Ultrafiltration failure, high transporter type	1	3.1%
Migration of the catheter	1	3.1%
Total	32	100%

Table 5: Frequency of non-infectious complications in the population of 80 children with ESRD on peritoneal dialysis

The study found as follows: of eight patients that presented abdominal hernia after the introduction of the catheter, three (37.5%) had a history of abdominal surgery; of three children who presented leakage of dialysate, two (66.7%) had had prior abdominal surgery; of seven children who presented ultrafiltration failure, seven (100%) had a history of peritonitis; of eight children who presented abdominal hernia, eight suffered from malnutrition and their albumin value was less than 3.5 mg/dL; of four children that presented outer cuff extrusion, three (75%) had a Tenckhoff two-cuff straight catheter. Finally, it was found that of 73 children who had no obstruction of the PD catheter, 71 (97.3%) had had a partial omentectomy (Table 5).

Discussion

Cayetano Heredia National Hospital is the only treatment center in Peru for chronic peritoneal dialysis where children with ESRD receive treatment through the Integral Insurance of Health (SIS) of the Ministry of Health.

In the study period of eight years, the population of children was 80. The average age at entry to PD was 10.3 years, which is similar to ages reported by a number of other studies: 8.2 years in Chile, 9 years in the USA, and 9.1 years in Turkey [11,15].

The present study reports the causes of ESRD in children receiving peritoneal dialysis and found that primary glomerulopathies was the most common. The study by Macchini et al. [10] reports the same finding, while in other studies obstructive uropathy and renal dysplasia predominate.

We found that the most frequent dialysis modality was chronic ambulatory peritoneal dialysis, as in other studies. These findings are similar to a Latin American study [13].

The Tenckhoff two-cuff spiral catheter was the most widely used, omentectomy was performed in 95% of patients, and the interval between the placement of the catheter and the beginning of PD was two weeks.

The causes of catheter replacement were infections, above all peritonitis and obstruction, as reported by other studies [10,12,15].

The frequency of noninfectious complications was 40.3% in 80 children over a period of eight years. This frequency is similar to that found in two Italian studies: Manchini et al. [10] report a frequency of 41% in 78 children over 17 years (1986-2002), and Rinaldi et al. [12] report a frequency of 33% in 363 children over 15 years (1986-2000). The latter study has more patients as it is based on the Italian registry of children with chronic peritoneal dialysis.

The opposite was found in a study from Brazil, where the frequency of non-infectious complications was 93%. The most frequent complications in the Brazilian study were failure of ultrafiltration, umbilical hernia, and obstruction; in others obstruction was also a

frequent complication, but not failure of ultrafiltration or umbilical hernia [10,27].

In our study, we found that some complications, such as abdominal hernia and leakage of dialysate, could be related to a history of abdominal surgery. Malnutrition and low serum albumin would relate to the presence of abdominal hernias. Ultrafiltration failure could be linked to a history of peritonitis; in the same manner, there might also be a relation between extrusions of the external cuff and the type of catheter used, such as the Tenckhoff two-cuff straight catheter [28-33]. Partial omentectomy at the time of putting the catheter in place could help prevent

obstruction, as already described in the literature: Macchini et al. [10], for example, found an association between omentectomy and no obstruction of the catheter ($p < 0.02$).

Therefore, we can conclude that the characteristics of pediatric patients and their noninfectious complications related to chronic peritoneal dialysis therapy in this series, excluding metabolic complications and electrolytes, are similar to those of other studies.
